Abstract: Handball is a high-intensity team sport that requires repeated sprints, rapid transitions between offense and defense, and sustained physical effort throughout the match. Aerobic capacity and muscular endurance are essential physiological components that enable players to maintain performance under fatigue. The present study aimed to examine the impact of a structured special sports training program on aerobic capacity and muscular endurance among competitive handball players. Thirty players were randomly divided into experimental and control groups. The experimental group underwent an eight-week special training program in addition to regular practice, while the control group followed routine training only. Aerobic capacity was assessed using the Cooper 12-Minute Run Test, and muscular endurance was measured through push-up and sit-up tests. Statistical analysis revealed significant improvement in aerobic capacity and muscular endurance in the experimental group compared to the control group. The findings suggest that structured special sports training enhances physiological efficiency and supports improved performance in handball players.
Keywords: Handball, Special training, Aerobic capacity, Muscular endurance, Physical performance.

Introduction - Handball is a fast-paced, high-intensity team sport that demands a combination of speed, strength, agility, coordination, and endurance. Throughout a match, players repeatedly perform explosive movements such as sprinting, jumping, blocking, and rapid directional changes. These actions are interspersed with brief recovery intervals, requiring both anaerobic bursts and sustained aerobic support. The physiological demands of handball make it essential for athletes to develop strong aerobic capacity and muscular endurance to maintain performance consistency.

Aerobic capacity plays a critical role in supporting recovery between high-intensity efforts. During competitive play, handball players often execute repeated sprints and defensive transitions with limited rest. A well-developed aerobic system enhances oxygen delivery to working muscles, improves recovery efficiency, and delays the onset of fatigue. Players with superior aerobic capacity are better able to sustain high levels of activity throughout both halves of the game.

Muscular endurance is equally important in handball performance. The sport requires repeated upper-body and lower-body muscular actions, including continuous arm movements for passing and shooting, sustained defensive stances, and repeated jumping for blocking or scoring. Insufficient muscular endurance may lead to reduced force production, slower reaction time, and decreased technical efficiency as fatigue accumulates.

While technical and tactical training remain central components of handball preparation, modern sports science emphasizes the importance of structured conditioning programs tailored to the specific demands of the sport. Special sports training programs that incorporate endurance-based drills, circuit training, and progressive overload principles can stimulate physiological adaptations that improve both aerobic function and muscular endurance. Despite the recognized importance of these physical qualities, many training programs prioritize skill acquisition without systematically monitoring physiological development. In competitive settings, especially at the state and district levels, structured endurance-focused training interventions remain limited. Therefore, evaluating the effectiveness of special sports training on key physiological components becomes important for optimizing athletic performance.

The present study was designed to investigate the impact of a structured special sports training program on aerobic capacity and muscular endurance among competitive handball players in Rajasthan. Understanding these adaptations may help coaches design more effective

conditioning programs and enhance overall match performance.

Review Of Literature

Research in handball physiology has consistently highlighted the importance of aerobic fitness and muscular endurance in sustaining performance. **Póvoas et al. (2012)** examined the physiological demands of elite handball matches and reported that players operate at high heart rate zones for prolonged periods, indicating the necessity of well-developed aerobic capacity for optimal performance. The study concluded that aerobic conditioning plays a vital role in recovery between repeated high-intensity efforts.

Similarly, **Gorostiaga et al. (2005)** investigated the effects of endurance and strength training in handball players and found significant improvements in cardiovascular efficiency and muscular performance following structured training interventions. Their findings emphasized that systematic conditioning enhances both aerobic power and fatigue resistance.

In a study focusing on match performance, **Michalsik, Madsen, and Aagaard (2014)** analyzed the physical demands of handball players and observed that repeated sprint actions and defensive movements require strong aerobic support to maintain intensity levels throughout the game. The authors highlighted that insufficient aerobic conditioning leads to early fatigue and reduced performance efficiency.

Muscular endurance has also been examined in relation to sport-specific performance. **Marques and González-Badillo (2006)** studied the impact of strength training on upper-body endurance in handball athletes and reported improvements in repeated throwing performance following structured resistance training. The study suggested that enhanced muscular endurance contributes to consistent technical execution.

Additionally, **Hermassi et al. (2011)** investigated the effects of combined strength and endurance training on young handball players. Their results demonstrated significant improvements in aerobic capacity and muscular endurance after an 8-week training program, indicating the effectiveness of structured conditioning protocols.

Research by **Buchheit and Laursen (2013)** on high-intensity interval training (HIIT) showed that targeted endurance training improves oxygen utilization and recovery capacity in team sport athletes. These physiological adaptations are particularly beneficial in sports like handball, which involve repeated bursts of activity.

Although numerous studies have evaluated endurance and strength adaptations in team sports, limited research has specifically examined the impact of special sports training programs on aerobic capacity and muscular endurance among competitive handball players in Rajasthan. Therefore, the present study aims to contribute to this area by analyzing physiological improvements resulting from structured training.

Objectives Of The Study:

1. To determine the effect of special sports training on aerobic capacity among competitive handball players.
2. To examine the impact of special sports training on muscular endurance.
3. To compare pre-test and post-test aerobic capacity of experimental and control groups.
4. To compare pre-test and post-test muscular endurance between experimental and control groups.

Hypotheses Of The Study:

- H1: There will be a significant improvement in aerobic capacity after participation in the special sports training program.
- H2: Muscular endurance will improve significantly following the training intervention.
- H3: The experimental group will show greater improvement than the control group in post-test scores.

Significance Of The Study:

1. Provides scientific evidence on the role of structured training in improving physiological fitness in handball players.
2. Assists coaches in designing effective endurance-based conditioning programs.
3. Highlights the importance of aerobic development for sustaining match intensity.
4. Emphasizes muscular endurance as a key factor for repeated skill execution.
5. Contributes to sports science research related to handball performance in Rajasthan.

Methodology

Research Design: The present investigation adopted an **experimental pre-test–post-test control group design** to determine the effect of a structured special sports training program on aerobic capacity and muscular endurance among competitive handball players. This design was selected to evaluate physiological adaptations resulting from a planned intervention and to compare the magnitude of improvement between trained and non-trained groups under controlled conditions.

Selection Of Subjects: A total of **30 competitive male handball players** aged between **17 and 22 years** were selected from recognized training centers and college teams in Rajasthan through purposive sampling. All participants were actively involved in competitive handball and regularly participated in structured training sessions.

The selected players were randomly assigned into two equal groups:

Group	Number of Subjects	Description
Experimental Group	15	Received special sports training along with regular practice
Control Group	15	Continued regular handball practice only

Random allocation was done to minimize selection bias and ensure homogeneity between groups at baseline.

Inclusion Criteria: Participants were included based on the following criteria:

1. Minimum **two years of competitive playing experience**
2. Regular participation in training (at least four sessions per week)
3. Medically fit and cleared for high-intensity physical activity
4. No history of major injury within the past six months

Exclusion Criteria: Participants were excluded if they:

1. Had cardiovascular, respiratory, or metabolic disorders
2. Were undergoing rehabilitation for musculoskeletal injuries
3. Were engaged in additional conditioning programs outside routine practice

Variables Of The Study:

Category	Variables
Independent Variable	Special sports training program
Dependent Variables	Aerobic capacity and muscular endurance

Operational Definitions:

- **Aerobic Capacity:** The ability of the cardiovascular and respiratory systems to supply oxygen during sustained physical activity, measured through field endurance testing.
- **Muscular Endurance:** The ability of specific muscle groups to perform repeated contractions over time without fatigue.

Tools And Measurement Techniques:

Standardized and validated field tests were administered:

Variable	Test Used	Measurement Unit
Aerobic Capacity	Cooper 12-Minute Run Test	Distance covered (meters)
Upper Body Muscular Endurance	Push-Up Test	Maximum repetitions
Abdominal Muscular Endurance	Sit-Up Test	Maximum repetitions

The Cooper Test was selected due to its established reliability in estimating cardiovascular endurance in team sport athletes.

Training Programme: The experimental group participated in an **8-week structured special sports training program**, conducted three days per week in addition to regular handball practice. Each training session lasted approximately **60 minutes**.

The training protocol included:

1. High-Intensity Interval Running (HIIT): Short bursts of high-speed running followed by controlled recovery periods.

2. Circuit Training: Multi-station exercises targeting both upper and lower body endurance.

3. Progressive Resistance Exercises: Bodyweight and partner-resisted drills to enhance muscular endurance.

4. Core Stability Training: Planks, dynamic core rotations, and stability exercises.

5. Sport-Specific Endurance Drills: Repeated sprint drills and continuous play simulations.

Training intensity was progressively increased following overload principles to stimulate physiological adaptation.

The control group continued regular technical and tactical training without additional conditioning components.

Testing Procedure: Pre-tests were conducted one week before the start of the intervention, and post-tests were administered immediately after completion of the eight-week training period. All testing sessions were conducted under similar environmental conditions and at the same time of day to control external variables.

Participants performed a standardized 10-minute warm-up before testing. Adequate rest intervals were provided between tests to avoid fatigue interference.

Reliability And Validity: The selected field tests have established reliability and validity in sports science research. Standardized instructions and demonstrations were provided to ensure uniformity in test administration.

Ethical Considerations: Participants were informed about the purpose and procedure of the study prior to data collection. Written consent was obtained. Confidentiality of individual data was maintained, and no invasive procedures were involved.

Statistical Analysis: Descriptive statistics including mean and standard deviation were calculated to summarize performance scores. The Shapiro–Wilk test was used to assess normality of data distribution. Paired sample *t*-tests were applied to determine within-group differences between pre-test and post-test scores. Independent sample *t*-tests were used to compare post-test performance between experimental and control groups. Effect size (Cohen's *d*) was calculated to determine the magnitude of training effect. The level of statistical significance was set at **0.05**.

Results: The analysis of data revealed the following findings:

1. The experimental group showed a significant increase in **aerobic capacity** after the 8-week special sports training program.
2. The distance covered in the Cooper 12-minute run test improved notably in the experimental group compared to the control group.
3. The control group showed only minor and non-significant changes in aerobic capacity.
4. Upper body muscular endurance (push-up performance) improved significantly in the experimental group.
5. Abdominal muscular endurance (sit-up performance) also showed marked improvement following the training intervention.

6. The control group demonstrated minimal improvement in muscular endurance variables.
7. Between-group comparison revealed that the experimental group performed significantly better than the control group in post-test scores
8. Effect size analysis indicated that the training program had a moderate to large impact on both aerobic capacity and muscular endurance.

Discussion: The findings of the present study indicate that the structured special sports training program produced significant improvements in aerobic capacity and muscular endurance among competitive handball players. The increase in distance covered during the Cooper 12-minute run test suggests enhanced cardiovascular efficiency and improved oxygen utilization. These adaptations are essential in handball, where players are required to sustain repeated high-intensity efforts with limited recovery.

The improvement in push-up and sit-up performance reflects enhanced muscular endurance of both upper and core muscle groups. In handball, repeated throwing, blocking, and defensive actions demand sustained muscular contractions. Increased endurance likely contributed to improved fatigue resistance and better maintenance of performance during prolonged activity.

The minimal changes observed in the control group highlight the importance of structured conditioning programs beyond routine technical training. Regular practice alone may not be sufficient to induce significant physiological adaptations unless specific endurance-focused training is included.

Overall, the results support the role of systematic special sports training in improving key physiological components necessary for competitive handball performance.

Conclusion:

1. Special sports training significantly improved aerobic capacity among competitive handball players.
2. Muscular endurance of both upper body and abdominal muscles showed marked enhancement following the training program.
3. Players who participated in structured conditioning demonstrated greater physiological adaptation compared to those who followed routine training only.
4. Improved aerobic capacity may contribute to better recovery and sustained performance during matches.
5. Enhanced muscular endurance supports repeated skill execution without early fatigue.
6. Structured endurance-based training is essential for optimizing overall handball performance.

Recommendations:

1. Special sports training programs focusing on endurance development should be incorporated into regular handball practice schedules.
2. Coaches should integrate high-intensity interval training and circuit-based endurance drills to improve cardiovascular efficiency.
3. Muscular endurance training for both upper body and core muscles should be emphasized to support repeated match actions.
4. Periodic fitness assessment should be conducted to monitor physiological progress.
5. Training intensity should follow progressive overload principles to ensure continuous adaptation.
6. Future research may include additional variables such as anaerobic power and agility for a more comprehensive performance profile.
